Abstract

In a partial monitoring game, the learner repeatedly chooses an action, the environment responds with an outcome, and then the learner suffers a loss and receives a feedback signal, both of which are fixed functions of the action and the outcome. The goal of the learner is to minimize his regret, which is the difference between his total cumulative loss and the total loss of the best fixed action in hindsight. Assuming that the outcomes are generated in an i.i.d. fashion from an arbitrary and unknown probability distribution, we characterize the minimax regret of any partial monitoring game with finitely many actions and outcomes. It turns out that the minimax regret of any such game is either zero, $\tilde{\Theta}(\sqrt{T})$, $\Theta(T^{2/3})$, or $\Theta(T)$. We provide a computationally efficient learning algorithm that achieves the minimax regret within logarithmic factor for any game.

1 Introduction

Partial monitoring provides a mathematical framework for sequential decision making problems with imperfect feedback. Various problems of interest can be modeled as partial monitoring instances, such as learning with expert advice [Littlestone and Warmuth, 1994], the multi-armed bandit problem [Auer et al., 2002], dynamic pricing [Kleinberg and Leighton, 2003], the dark pool problem [Agarwal et al., 2010], label efficient prediction [Cesa-Bianchi et al., 2005], and linear and convex optimization with full or bandit feedback [Zinkevich, 2003, Abernethy et al., 2008, Flaxman et al., 2005].

In this paper we restrict ourselves to finite games, i.e., games where both the set of actions available to the learner and the set of possible outcomes generated by the environment are finite. A finite partial monitoring game $G$ is described by a pair of $N \times M$ matrices: the loss matrix $L$ and the feedback matrix $H$. The entries $\ell_{i,j}$ of $L$ are real numbers lying in, say, the interval $[0, 1]$. The entries $h_{i,j}$ of $H$ belong to an alphabet $\Sigma$ on which we do not impose any structure and we only assume that learner is able to distinguish distinct elements of the alphabet.

The game proceeds in $T$ rounds according to the following protocol. First, $G = (L, H)$ is announced for both players. In each round $t = 1, 2, \ldots, T$, the learner chooses an action $I_t \in \{1, 2, \ldots, N\}$ and simultaneously, the environment chooses an outcome $J_t \in \{1, 2, \ldots, M\}$. Then, the learner receives as a feedback the entry $h_{I_t, J_t}$. The learner incurs instantaneous loss $\ell_{I_t, J_t}$, which is not revealed to him. The feedback can be thought of as a masked information about the outcome $J_t$. In some cases $h_{I_t, J_t}$ might uniquely determine the outcome, in other cases the feedback might give only partial or no information about the outcome. In this paper, we shall assume that $J_t$ is chosen randomly from a fixed multinomial distribution.

The learner is scored according to the loss matrix $L$. In round $t$ the learner incurs an instantaneous loss of $\ell_{I_t, J_t}$. The goal of the learner is to keep low his total loss $\sum_{t=1}^{T} \ell_{I_t, J_t}$. Equivalently, the learner’s performance can also be measured in terms of his regret, i.e., the total loss of the learner is compared with the loss of best fixed action in hindsight. The regret is defined as the difference of these two losses.

In general, the regret grows with the number of rounds $T$. If the regret is sublinear in $T$, the learner is said to be Hannan consistent, and this means that the learner’s average per-round loss approaches the average per-round loss of the best action in hindsight.

Piccolboni and Schindelhauer (2001) were one of the first to study the regret of these games. In fact, they have studied the problem without making any probabilistic assumptions about the outcome sequence $J_t$.
They proved that for any finite game \((L, H)\), either for any algorithm the regret can be \(\Omega(T)\) in the worst case, or there exists an algorithm which has regret \(O(T^{3/4})\) on any outcome sequence. This result was later improved by Cesa-Bianchi et al. (2006) who showed that the algorithm of Piccolboni and Schindelhauer has regret \(O(T^{2/3})\). Furthermore, they provided an example of a finite game, a variant of label-efficient prediction, for which any algorithm has regret \(\Theta(T^{2/3})\) in the worst case.

However, for many games \(O(T^{2/3})\) is not optimal. For example, games with full feedback (i.e., when the feedback uniquely determines the outcome) can be viewed as a special instance of the problem of learning with expert advice and in this case it is known that the “EWA forecaster” has regret \(O(\sqrt{T})\); see e.g., Lugosi and Cesa-Bianchi (2006, Chapter 3). Similarly, for games with “bandit feedback” (i.e., when the feedback determines the instantaneous loss) the INF algorithm (Audibert and Bubeck, 2009) and the Exp3 algorithm (Auer et al., 2002) achieve \(O(\sqrt{T})\) regret as well.

This leaves open the problem of determining the minimax regret (i.e., optimal worst-case regret) of any given game \((L, H)\). A partial progress was made in this direction by Bartók et al. (2010) who characterized (almost) all finite games with \(M = 2\) outcomes. They showed that any minimax regret of any “non-degenerate” finite game with two outcomes falls into one of four categories: zero, \(\Theta(\sqrt{T})\), \(\Theta(T^{2/3})\) or \(\Theta(T)\). They gave a combinatoric-geometric condition on the matrices \(L, H\) which determines the category a game belongs to. Additionally, they constructed an efficient algorithm which, for any game, achieves the minimax regret rate associated to the game within poly-logarithmic factor.

In this paper, we consider the same problem, with two exceptions. In pursuing a general result, we will consider all finite games. However, at the same time, we will only deal with stochastic environments, i.e., when the outcome sequences are generated from a fixed probability distribution in an i.i.d. manner.

The regret against stochastic environments is defined as the difference between the cumulative loss suffered by the algorithm and the action with the lowest expected loss. That is, given an algorithm \(A\) and a time horizon \(T\), if the outcomes are generated from a probability distribution \(p\), the regret is

\[
R_T(A, p) = \sum_{t=1}^{T} \ell_{t, J_t} - \min_{1 \leq i \leq N} \mathbb{E}_p \left[ \sum_{t=1}^{T} \ell_{i, J_t} \right].
\]

In this paper we analyze the minimax expected regret (in what follows, minimax regret) of games, defined as

\[
R_T(G) = \inf_{A} \sup_{p \in \Delta_M} \mathbb{E}_p [R_T(A, p)].
\]

We show that the minimax regret of any finite game falls into four categories: zero, \(\Theta(\sqrt{T})\), \(\Theta(T^{2/3})\), or \(\Theta(T)\). Accordingly, we call the games trivial, easy, hard, and hopeless. We give a simple and efficiently computable characterization of these classes using a geometric condition on \((L, H)\). We provide lower-bounds and algorithms that achieve them within poly-logarithmic factor. Our result is an extension of the result of Bartók et al. (2010) for stochastic environments.

It is clear that any lower bound which holds for stochastic environments must hold for adversarial environments too. On the other hand, algorithms and regret upper bounds for stochastic environments, of course, do not transfer to algorithms and regret upper bounds for the adversarial case. Our characterization is a stepping stone towards understanding the minimax regret of partial monitoring games. In particular, we conjecture that our characterization holds without any change for unrestricted environments.

2 Preliminaries

In this section, we introduce our conventions, along with some definitions. By default, all vectors are column vectors. We denote by \(\|v\| = \sqrt{v^T v}\) the Euclidean norm of a vector \(v\). For a vector \(v\), the notation \(v \geq 0\) means that all entries of \(v\) are non-negative, and the notation \(v > 0\) means that all entries are positive. For a matrix \(A\), \(\text{Im} A\) denotes its image space, i.e., the vector space generated by its columns, and the notation \(\text{Ker} A\) denotes its kernel, i.e., the set \(\{x : Ax = 0\}\).

Consider a game \(G = (L, H)\) with \(N\) actions and \(M\) outcomes. That is, \(L \in \mathbb{R}^{N \times M}\) and \(H \in \Sigma^{N \times M}\). For the sake of simplicity and, without loss of generality, we assume that no symbol \(\sigma \in \Sigma\) can be present in two different rows of \(H\). The signal matrix of an action is defined as follows:

\[\text{Definition 1 (Signal matrix)}\] Let \(\{\sigma_1, \ldots, \sigma_{s_i}\}\) be the set of symbols listed in the \(i^{th}\) row of \(H\). (Thus, \(s_i\) denotes the number of different symbols in row \(i\) of \(H\).) The signal matrix \(S_i\) of action \(i\) is defined as an

---

1. The notations \(\tilde{O}(\cdot)\) and \(\Theta(\cdot)\) hide polylogarithmic factors.
2. We ignore the dependence of regret on the number of actions or any other parameters.
Definition 3 (Observability) In this section, we are now equipped to define a notion which will play a key role in the classification theorem: monitoring games based on how their minimax regret scales with the time horizon. Thanks to the previous

In this section we present our main result: we state the theorem that classifies all finite stochastic partial-monitoring games based on how their minimax regret scales with the time horizon. Thanks to the previous

Definition 2 (Cell decomposition) For an action \( i \), the cell \( C_i \) associated with \( i \) is defined as \( C_i = \{ p \in \Delta_M : \text{ action } i \text{ is optimal under } p \} \). The cell decomposition of \( \Delta_M \) is defined as the multiset \( C = \{ C_i : 1 \leq i \leq N, \ C_i \text{ has positive } (M-1)\text{-dimensional volume} \} \).

Actions whose cell is of positive \((M-1)\)-dimensional volume are called strongly Pareto-optimal. Actions that are Pareto-optimal but not strongly Pareto-optimal are called degenerate. Note that the cells of the actions are defined with linear inequalities and thus they are convex polytopes. It follows that strongly Pareto-optimal actions are the actions whose cells are \((M-1)\)-dimensional polytopes. It is also important to note that the cell decomposition is a multiset, since some actions can share the same cell. Nevertheless, if two actions have the same cell of dimension \((M-1)\), their loss vectors will necessarily be identical.

We call two cells of \( C \) neighbors if their intersection is an \((M-2)\)-dimensional polytope. The actions corresponding to these cells will also be called neighbors. Neighborship is not defined for cells outside of \( C \). For two neighboring cells \( C_i, C_j \in C \), we define the neighborhood action set \( A_{i,j} = \{ 1 \leq k \leq N : C_i \cap C_j \subseteq C_k \} \). It follows from the definition that actions \( i \) and \( j \) are in \( A_{i,j} \) and thus \( A_{i,j} \) is nonempty. However, one can have more than two actions in the neighborhood action set.

When discussing lower bounds we will need the definition of algorithms. For us, an algorithm \( A \) is a mapping \( A : \Sigma^* \to \{ 1, 2, \ldots, N \} \) which maps past feedback sequences to actions. That the algorithms are deterministic is assumed for convenience. In particular, the lower bounds we prove can be extended to randomized algorithms by conditioning on the internal randomization of the algorithm. Note that the algorithms we design are themselves deterministic.

3 Classification of finite partial-monitoring games

In this section we present our main result: we state the theorem that classifies all finite stochastic partial-monitoring games based on how their minimax regret scales with the time horizon. Thanks to the previous section, we are now equipped to define a notion which will play a key role in the classification theorem:

Definition 3 (Observability) Let \( S \) be the signal matrix for the set of all actions in the game. For actions \( i \) and \( j \), we say that \( \ell_i - \ell_j \) is globally observable if \( \ell_i - \ell_j \in \text{Im} S^1 \). Furthermore, if \( i \) and \( j \) are two neighboring actions, then \( \ell_i - \ell_j \) is called locally observable if \( \ell_i - \ell_j \in \text{Im} S^T_{(i,j)} \), where \( S_{(i,j)} \) is the signal matrix for the neighborhood action set \( A_{i,j} \).

As we will see, global observability implies that we can estimate the difference of the expected losses after choosing each action once. Local observability means we only need actions from the neighborhood action set to estimate the difference.

The classification theorem, which is our main result, is the following:

Theorem 4 (Classification) Let \( G = (L, H) \) be a partial-monitoring game with \( N \) actions and \( M \) outcomes. Let \( C = \{ C_1, \ldots, C_k \} \) be its cell decomposition, with corresponding loss vectors \( \ell_1, \ldots, \ell_k \). The game \( G \) falls into one of the following four categories:

(a) \( R_T(G) = 0 \) if there exists an action \( i \) with \( C_i = \Delta_M \). This case is called trivial.

(b) \( R_T(G) = \Theta(T) \) if there exist two strongly Pareto-optimal actions \( i \) and \( j \) such that \( \ell_i - \ell_j \) is not globally observable. This case is called hopeless.

(c) \( R_T(G) = \widetilde{\Theta}(\sqrt{T}) \) if it is not trivial and for all pairs of (strongly Pareto-optimal) neighboring actions \( i \) and \( j \), \( \ell_i - \ell_j \) is locally observable. These games are called easy.

3One could think that actions with identical loss vectors are redundant and that all but one of such actions could be removed without loss of generality. However, since different actions can lead to different observations and thus yield different information, removing the duplicates can be harmful.
Figure 1: Partial monitoring games and their minimax regret as it was known previously. The big rectangle
denotes the set of all games. Inside the big rectangle, the games are ordered from left to right based on their
minimax regret. In the “hard” area, l.e.p. denotes label-efficient prediction. The grey area contains games
whose minimax regret is between \( \Omega(\sqrt{T}) \) and \( O(T^{2/3}) \) but their exact regret rate was unknown. This area is
now eliminated, and the dynamic pricing problem is proven to be hard.

(d) \( R_T(G) = \Theta(T^{2/3}) \) if \( G \) is not hopeless and there exists a pair of neighboring actions \( i \) and \( j \) such that
\( \ell_i - \ell_j \) is not locally observable. These games are called hard.

Note that the conditions listed under (a)–(d) are mutually exclusive and cover all finite partial-monitoring
games. The only non-obvious implication is that if a game is easy then it cannot be hopeless. The reason this
holds is because for any pair of cells \( C_i, C_j \) in \( C \), the vector \( \ell_i - \ell_j \) can be expressed as a telescoping sum of
the differences of loss vectors of neighboring cells.

The remainder of the paper is dedicated to proving Theorem 4. We start with the simple cases. If there
exists an action whose cell covers the whole probability simplex then choosing that action in every round will
yield zero regret, proving case (a). The condition in Case (b) is due to Piccolboni and Schindelhauer (2001),
who showed that under the condition mentioned there, there is no algorithm that achieves sublinear regret.
The upper bound for case (c) is achieved by the FeedExp3 algorithm due to Piccolboni and Schindelhauer
(2001), for which a regret bound of \( O(T^{2/3}) \) was shown by Cesa-Bianchi et al. (2006). The lower bound for
case (c) was proved by Antos et al. (2011). For a visualization of previous results, see Figure 1.

The above assertions help characterize trivial and hopeless games, and show that if a game is not trivial
and not hopeless then its minimax regret falls between \( \Omega(\sqrt{T}) \) and \( O(T^{2/3}) \). Our contribution in this paper
is that we give exact minimax rates (up to logarithmic factors) for these games. To prove the upper bound for
case (c), we introduce a new algorithm, which we call BALATON, for “Bandit Algorithm for Loss Annihilation”.
This algorithm is presented in Section 4, while its analysis is given in Section 5. The lower bound for
case (d) is presented in Section 6.

3.1 Example
In this section, as a corollary of Theorem 4, we show that the discretized dynamic pricing game (see, e.g.,
Cesa-Bianchi et al. (2006)) is hard. Dynamic pricing is a game between a vendor (learner) and a customer
(environment). In each round, the vendor sets a price he wants to sell his product at (action), and the costumer
sets a maximum price he is willing to buy the product (outcome). If the product is not sold, the vendor suffers
some constant loss, otherwise his loss is the difference between the customer’s maximum and his price. The
customer never reveals the maximum price and thus the vendor’s only feedback is whether he sold the product
or not.

The discretized version of the game with \( N \) actions (and outcomes) is defined by the matrices

\[
L = \begin{pmatrix}
0 & 1 & 2 & \cdots & N - 1 \\
c & 0 & 1 & \cdots & N - 2 \\
\vdots & \ddots & \ddots & \ddots & \vdots \\
c & \cdots & c & 0 & 1 \\
c & \cdots & \cdots & c & 0
\end{pmatrix},
\]

\[
H = \begin{pmatrix}
1 & \cdots & \cdots & \cdots & 1 \\
0 & \ddots & \ddots & \ddots & \vdots \\
\vdots & \ddots & \ddots & \ddots & \vdots \\
0 & \cdots & \cdots & 0 & 1
\end{pmatrix},
\]

where \( c \) is a positive constant (see Figure 2 for the cell-decomposition for \( N = 3 \)). It is easy to see that all
the actions are strongly Pareto-optimal. Also, after some linear algebra it turns out that the cells underlying
the actions have a single common vertex in the interior of the probability simplex. It follows that any two
actions are neighbors. On the other hand, if we take two non-consecutive actions \( i \) and \( i' \), \( \ell_i - \ell_{i'} \) is not

\footnote{Although Piccolboni and Schindelhauer state their theorem for adversarial environments, their proof applies to
stochastic environments without any change (which is important for the lower bound part).}

\footnote{Balaton is a lake in Hungary. We thank Gergely Neu for suggesting the name.}
Theorem 4, we have that for all neighboring cells \(A_a\) since the probability simplex is convex and the cell decomposition covers the simplex. The graph has an edge between vertices whose corresponding cells are neighbors. This graph is connected, define a graph \(G_\delta\) an error probability \(S\). That is, if \(L\) the input of the algorithm is the loss matrix \(L\). The feedback at time step \(t\) \(R\) of alive actions and their neighborship graph \(O\) is the observation vector \(I\). For example, the signal matrix for action 1 and action \(N\) is

\[
S_{(1,N)} = \begin{pmatrix}
1 & \ldots & 1 & 1 \\
1 & \ldots & 1 & 0 \\
0 & \ldots & 0 & 1
\end{pmatrix},
\]

whereas \(\ell_N - \ell_1 = (c, c - 1, \ldots, c - N + 2, -N + 1)^T\). It is obvious that \(\ell_N - \ell_1\) is not in the row space of \(S_{(1,N)}\).

## 4 BALATON: An algorithm for easy games

In this section we present our algorithm that achieves \(O(\sqrt{T})\) expected regret for easy games (case (c) of Theorem 4). The input of the algorithm is the loss matrix \(L\), the feedback matrix \(H\), the time horizon \(T\) and an error probability \(\delta\), to be chosen later. Before describing the algorithm, we introduce some notation. We define a graph \(G\) associated with game \(G\) the following way. Let the vertex set be the set of cells of the cell decomposition \(C\) of the probability simplex such that cells \(C_i, C_j \in C\) share the same vertex when \(C_i = C_j\). The graph has an edge between vertices whose corresponding cells are neighbors. This graph is connected, since the probability simplex is convex and the cell decomposition covers the simplex.

Recall that for neighboring cells \(C_i, C_j\), the signal matrix \(S_{(i,j)}\) is defined as the signal matrix for the neighborhood action set \(A_{i,j}\) of cells \(i, j\). Assuming that the game satisfies the condition of case (c) of Theorem 4, we have that for all neighboring cells \(C_i\) and \(C_j\), \(\ell_i - \ell_j \in \text{Im} S_{(i,j)}\). This means that there exists a coefficient vector \(v_{(i,j)}\) such that \(\ell_i - \ell_j = S^T_{(i,j)}v_{(i,j)}\). We define the \(k\)th segment of \(v_{(i,j)}\), denoted by \(v_{(i,j),k}\), as the vector of components of \(v_{(i,j)}\) that correspond to the \(k\)th action in the neighborhood action set. That is, if \(S^T_{(i,j)} = (S_1^T \ldots S_r^T)\), then \(\ell_i - \ell_j = S^T_{(i,j)}v_{(i,j)} = \sum_{s=1}^r S_s^T v_{(i,j),s}\), where \(S_1, \ldots, S_r\) are the signal matrices of the individual actions in \(A_{i,j}\).

Let \(J_t \in \{1, \ldots, M\}\) denote the outcome at time step \(t\). For \(1 \leq k \leq M\), let \(e_k \in \mathbb{R}^M\) be the \(k\)th unit vector. For an action \(i\), let \(O_i(t) = S_i e_{J_t}\) be the observation vector of action \(i\) at time step \(t\). If the rows of the signal matrix \(S_i\) correspond to symbols \(\sigma_1, \ldots, \sigma_s\) and action \(i\) is chosen at time step \(t\) then the unit vector \(O_i(t)\) indicates which symbol was observed in that time step. Thus, \(O_i(t)\) holds the same information as the feedback at time \(t\) (recall that \(J_t\) is the action chosen by the learner at time step \(t\)). From now on, for simplicity, we will assume that the feedback at time step \(t\) is the observation vector \(O_{J_t}(t)\) itself.

The main idea of the algorithm is to successively eliminate actions in an efficient, yet safe manner. When all remaining strongly Pareto optimal actions share the same cell, the elimination phase finishes and from this point, one of the remaining actions is played. During the elimination phase, the algorithm works in rounds. In each round each ‘alive’ Pareto optimal action is played once. The resulting observations are used to estimate the loss-difference between the alive actions. If some estimate becomes sufficiently precise, the action of the pair deemed to be suboptimal is eliminated (possibly together with other actions). To determine if an estimate is sufficiently precise, we will use an appropriate stopping rule. A small regret will be achieved by tuning the error probability of the stopping rule appropriately.

The details of the algorithm are as follows: In the preprocessing phase, the algorithm constructs the neighbourhood graph, the signal matrices \(S_{(i,j)}\) assigned to the edges of the graph, the coefficient vectors \(v_{(i,j)}\) and their segment vectors \(v_{(i,j),k}\). In addition, it constructs a path in the graph connecting any pairs of nodes, and initializes some variables used by the stopping rule.

In the elimination phase, the algorithm runs a loop. In each round of the loop, the algorithm chooses each of the alive actions once and, based on the observations, the estimates \(\hat{\mu}_{(i,j)}\) of the loss-differences \((\ell_i - \ell_j)^T p^*\) are updated, where \(p^*\) is the actual opponent strategy. The algorithm maintains the set \(C\) of cells of alive actions and their neighborship graph \(G\).
Here, alive actions once. (deterministic) upper bound on their range. Here \( p > 1 \) is an arbitrarily chosen parameter of the algorithm, \( \sigma \) is a (deterministic) upper bound on the (conditional) variance of the random variables whose common mean \( \mu \) we wish to estimate, while \( R \) is a (deterministic) upper bound on their range. This is a general stopping rule method, which stops when it
produced an $\epsilon$-relative accurate estimate of the unknown mean. The algorithm is guaranteed to be correct outside of a failure event whose probability is bounded by $\delta$.

Algorithm BALATON calls this method with $\varepsilon = 1/2$. As a result, when BSTOPSTEP returns true, outside of the failure event the sign of the estimate $\hat{\mu}$ supplied to BALATON will match the sign of the mean to be estimated. The conditions under which the algorithm indeed produces $\varepsilon$-accurate estimates (with high probability) are given in Lemma 11 (see Appendix), which also states that also with high probability, the time when the algorithm stops is bounded by

$$C \cdot \max\left(\frac{\sigma^2}{e^2|\mu|^2}, \frac{R}{|\mu|}\right) \left(\log\frac{1}{\delta} + \log\frac{R}{|\mu|}\right),$$

where $\mu \neq 0$ is the true mean. Note that the choice of $p$ in (1) influences only $C$.

If BSTOPSTEP returns true for an estimate $\hat{\mu}_{i,j}$, function ELIMINATE is called. If, say, $\mu_{i,j} > 0$, this function takes the closed half space $\{q \in \Delta_M : (\ell_i - \ell_j)^\top q \leq 0\}$ and eliminates all actions whose cell lies completely in the half space. The function also drops the vertices from the graph that correspond to eliminated cells. The elimination necessarily concerns all actions with corresponding cell $C_i$, and possibly other actions as well. The remaining cells are redefined by taking their intersection with the complement half space $\{q \in \Delta_M : (\ell_i - \ell_j)^\top q \geq 0\}$.

By construction, after the elimination phase, the remaining graph is still connected, but some paths used in the round may have lost vertices or edges. For this reason, in the last phase of the round, new paths are constructed for vertex pairs with broken paths.

The main loop of the algorithm continues until either one vertex remains in the graph or the time horizon $T$ is reached. In the former case, one of the actions corresponding to that vertex is chosen until the time horizon is reached.

## 5 Analysis of the algorithm

In this section we prove that the algorithm described in the previous section achieves $\tilde{O}(\sqrt{T})$ expected regret.

Let us assume that the outcomes are generated following the probability vector $p^* \in \Delta_M$. Let $j^*$ denote an optimal action, that is, for every $1 \leq i \leq N$, $\ell_i^\top p^* \leq \ell_j^\top p^*$. For every pair of actions $i, j$, let $\alpha_{i,j} = (\ell_i - \ell_j)^\top p^*$ be the expected difference of their instantaneous loss. The expected regret of the algorithm can be rewritten as

$$\mathbb{E}\left[\sum_{t=1}^{T} \ell_{I_t,J_t} - \min_{1 \leq i \leq N} \mathbb{E}\left[\sum_{t=1}^{T} \ell_i, J_t\right]\right] = \sum_{i=1}^{N} \mathbb{E}[\tau_i] \alpha_{i,j^*},$$

where $\tau_i$ is the number of times action $i$ is chosen by the algorithm.

Throughout the proof, the value that BALATON assigns to a variable $x$ in round $n$ will be denoted by $x(n)$. Further, for $1 \leq k \leq N$, we introduce the i.i.d. random sequence $(J_k(n))_{n \geq 1}$, taking values on $\{1, \ldots, M\}$, with common multinomial distribution satisfying, $\mathbb{P}[J_k(n) = j] = p_j^*$. Clearly, a statistically equivalent model to the one where $(J_t)$ is an i.i.d. sequence with multinomial $p^*$ is when $(J_t)$ is defined through

$$J_k = J_t, \left(\sum_{s=1}^{t} \mathbb{I}(I_s = I_t)\right).$$

Note that this claim holds, independently of the algorithm generating the actions, $I_t$. Therefore, in what follows, we assume that the outcome sequence is generated through (3). As we will see, this construction significantly simplifies subsequent steps of the proof. In particular, the construction will be very convenient since if action $k$ is selected by our algorithm in the $n^{th}$ elimination round then the outcome obtained in response is going to be $O_k(n) = S_k \mathbb{I}(k = n)$, where $u_k(n) = \ell_k, n)$. (This holds because in the elimination rounds all alive actions are tried exactly once by BALATON.)

Let $(\mathcal{F}_n)_n$ be the filtration defined as $\mathcal{F}_n = \sigma(\{u_k(m), 1 \leq k \leq N, 1 \leq m \leq n\})$. We also introduce the notations $E_n[\cdot] = E[\cdot|\mathcal{F}_n]$ and $\text{Var}_n[\cdot] = \text{Var}(\cdot|\mathcal{F}_n)$, the conditional expectation and conditional variance

---

### Algorithm 2 Algorithm BSTOPSTEP

Input: $\hat{\mu}, \text{LB}, \text{UB}, \sigma, R, n, \varepsilon, \delta$

\[
\text{LB} \leftarrow \max(\text{LB}, |\hat{\mu}| - c(\delta, \sigma, R, n)) \\
\text{UB} \leftarrow \min(\text{UB}, |\hat{\mu}| + c(\delta, \sigma, R, n)) \\
\text{return } (1 + c)\text{LB} < (1 - c)\text{UB}
\]
operators corresponding to \( F_n \). Note that \( F_n \) contains the information known to BALATON (and more) at the end of the elimination round \( n \). Our first (trivial) observation is that \( \mu_{(i,j)}(n) \), the estimate of \( \alpha_{i,j} \) obtained in round \( n \) is \( F_n \)-measurable. The next lemma establishes that, furthermore, \( \mu_{(i,j)}(n) \) is an unbiased estimate of \( \alpha_{i,j} \).

**Lemma 5** For any \( n \geq 1 \) and \( i, j \) such that \( C_i, C_j \in C \), \( \mathbb{E}_{n-1}[\mu_{(i,j)}(n)] = \alpha_{i,j} \).

**Proof:** Consider first the case when actions \( i \) and \( j \) are neighbors. In this case,

\[
\mu_{(i,j)}(n) = \sum_{k \in A_{i,j}} O_k(n)^T v_{(i,j),k} = \sum_{k \in A_{i,j}} (S_k u_k(n))^T v_{(i,j),k} = \sum_{k \in A_{i,j}} u_k(n)^T S_k^T v_{(i,j),k},
\]

and thus

\[
\mathbb{E}_{n-1} \left[ \mu_{(i,j)}(n) \right] = \sum_{k \in A_{i,j}} \mathbb{E}_{n-1} \left[ u_k(n)^T \right] S_k^T v_{(i,j),k} = \mathbb{E}_{n-1} \left[ p^T \sum_{k \in A_{i,j}} S_k^T v_{(i,j),k} \right] = \mathbb{E}_{n-1} \left[ p^T S_{(i,j)} v_{(i,j)} \right] = p^T (\ell_i - \ell_j) = \alpha_{i,j}.
\]

For non-adjacent \( i \) and \( j \), we have a telescoping sum:

\[
\mathbb{E}_{n-1} \left[ \mu_{(i,j)}(n) \right] = \sum_{k=1}^{r} \mathbb{E}_{n-1} \left[ \mu_{(i_{k-1},i_k)}(n) \right] = p^T (\ell_{i_0} - \ell_{i_1} + \ell_{i_1} - \ell_{i_2} + \ldots + \ell_{i_r} - \ell_{i_r}) = \alpha_{i,j},
\]

where \( i = i_0, i_1, \ldots, i_r, j = i_r \) is the path the algorithm uses in round \( n \), known at the end of round \( n - 1 \). \( \blacksquare \)

**Lemma 6** The conditional variance of \( \mu_{(i,j)}(n) \), \( \mathbb{V}_{n-1}(\mu_{(i,j)}(n)) \), is upper bounded by

\[
V = 2 \sum_{\{i,j \text{ neighbors}\}} \| v_{(i,j)} \|_2^2.
\]

**Proof:** For neighboring cells \( i, j \), we write

\[
\mu_{(i,j)}(n) = \sum_{k \in A_{i,j}} O_k(n)^T v_{(i,j),k} \quad \text{and thus}
\]

\[
\mathbb{V}_{n-1}(\mu_{(i,j)}(n)) = \mathbb{V}_{n-1} \left( \sum_{k \in A_{i,j}} O_k(n)^T v_{(i,j),k} \right) = \sum_{k \in A_{i,j}} \mathbb{E}_{n-1} \left[ v_{(i,j),k}^T (O_k(n) - \mathbb{E}_{n-1}[O_k(n)]) (O_k(n) - \mathbb{E}_{n-1}[O_k(n)])^T v_{(i,j),k} \right]
\]

\[
\leq \sum_{k \in A_{i,j}} \| v_{(i,j),k} \|_2^2 \mathbb{E}_{n-1} \left[ \| O_k(n) - \mathbb{E}_{n-1}[O_k(n)] \|_2^2 \right]
\]

\[
\leq \sum_{k \in A_{i,j}} \| v_{(i,j),k} \|_2^2 = \| v_{(i,j)} \|_2^2.
\]

where in (4) we used that \( O_k(n) \) is a unit vector and \( \mathbb{E}_{n-1}[O_k(n)] \) is a probability vector.

For \( i, j \) non-neighboring cells, let \( i = i_0, i_1, \ldots, i_r = j \) be the path used for the estimate in round \( n \). Then \( \mu_{(i,j)}(n) \) can be written as

\[
\mu_{(i,j)}(n) = \sum_{s=1}^{r} \mu_{(i_{s-1},i_s)}(n) = \sum_{s=1}^{r} \sum_{k \in A_{i_{s-1},i_s}} O_k(n)^T v_{(i_{s-1},i_s),k}.
\]

It is not hard to see that an action can only be in at most two neighborhood action sets in the path and so the double sum can be rearranged as

\[
\sum_{k \in \bigcup_{i_{s-1},i_s} A_{i_{s-1},i_s}} O_k(n)^T (v_{(i_{s-1},i_s),k} + v_{(i_{s-1},i_{s+1}),k}),
\]

and thus \( \mathbb{V}_{n-1} (\mu_{(i,j)}(n)) \leq 2 \sum_{s=1}^{r} \| v_{(i_{s-1},i_s)} \|_2^2 \leq 2 \sum_{\{i,j \text{ neighbors}\}} \| v_{(i,j)} \|_2^2. \) \( \blacksquare \)

**Lemma 7** The range of the estimates \( \mu_{(i,j)}(n) \) is upper bounded by \( R = \sum_{\{i,j \text{ neighbors}\}} \| v_{(i,j)} \|_1. \)
Proof: The bound trivially follows from the definition of the estimates.

Let \( \delta \) be the confidence parameter used in BStopStep. Since, according to Lemmas 5, 6 and 7 \( (\mu_{i,j}) \) is a “shifted” martingale difference sequence with conditional mean \( \alpha_{i,j} \), bounded conditional variance and range, we can apply Lemma 11 stated in the Appendix. By the union bound, the probability that any of the confidence bounds fails during the game is at most \( N^2 \delta \). Thus, with probability at least \( 1 - N^2 \delta \), if BStopStep returns true for a pair \((i, j)\) then \( \text{sgn}(\alpha_{i,j}) = \text{sgn}(\mu_{i,j}) \) and the algorithm eliminates all the actions whose cell is contained in the closed half space defined by \( \mathcal{H} = \{ p : \text{sgn}(\alpha_{i,j}) p^\top (\ell_i - \ell_j) \leq 0 \} \).

By definition \( \alpha_{i,j} = (\ell_i - \ell_j)^\top p^* \). Thus \( p^* \notin \mathcal{H} \) and none of the eliminated actions can be optimal under \( p^* \).

From Lemma 11 we also see that, with probability at least \( 1 - N^2 \delta \), the number of times \( \tau_{i}^\ast \) the algorithm experiments with a suboptimal action \( i \) during the elimination phase is bounded by
\[
\tau_{i}^\ast \leq \frac{c(G)}{\alpha_{i,j}^\ast} \log \frac{R}{\delta \alpha_{i,j}^\ast} = T_i,
\]
where \( c(G) = C(V + R) \) is a problem dependent constant.

The following lemma, the proof of which can be found in the Appendix, shows that degenerate actions will be eliminated in time.

**Lemma 8** Let action \( i \) be a degenerate action. Let \( A_i = \{ j : C_j \in C, C_i \subset C_j \} \). The following two statements hold:

1. If any of the actions in \( A_i \) is eliminated, then action \( i \) is eliminated as well.
2. There exists an action \( k_i \in A_i \) such that \( \alpha_{k_i,j}^\ast \geq \alpha_{i,j}^\ast \).

An immediate implication of the first claim of the lemma is that if action \( k_i \) gets eliminated then action \( i \) gets eliminated as well, that is, the number of times action \( i \) is chosen cannot be greater than that of action \( k_i \). Hence, \( \tau_{i}^\ast \leq \tau_{k_i}^\ast \).

Let \( \mathcal{E} \) be the complement of the failure event underlying the stopping rules. As discussed earlier, \( \mathbb{P}(\mathcal{E}^c) \leq N^2 \delta \). Note that on \( \mathcal{E} \), i.e., when the stopping rules do not fail, no suboptimal action can remain for the final phase. Hence, \( \tau_i^\ast \mathbb{P}(\mathcal{E}) \leq \tau_i^\ast \mathbb{P}(\mathcal{E}) \), where \( \tau_i \) is the number of times action \( i \) is chosen by the algorithm. To upper bound the expected regret we continue from (2) as
\[
\sum_{i=1}^{N} \mathbb{E}[\tau_i \alpha_{i,j}^\ast] = \sum_{i=1}^{N} \mathbb{E}[\mathbb{I}(\mathcal{E}) \tau_i \alpha_{i,j}^\ast + \mathbb{P}(\mathcal{E}^c)T] \quad \text{(because } \sum_{i=1}^{N} \tau_i = T \text{ and } 0 \leq \alpha_{i,j}^\ast \leq 1)\]
\[
\leq \sum_{i=1}^{N} \mathbb{E}[\mathbb{I}(\mathcal{E}) \tau_i^\ast \alpha_{i,j}^\ast + N^2 \delta T] 
\leq \sum_{i \in C_i \in \mathcal{E}} \mathbb{E}[\mathbb{I}(\mathcal{E}) \tau_i^\ast \alpha_{i,j}^\ast + \sum_{i \in C_i \in \mathcal{E}} \mathbb{E}[\mathbb{I}(\mathcal{E}) \tau_i^\ast \alpha_{i,j}^\ast + N^2 \delta T] 
\leq \sum_{i \in C_i \in \mathcal{E}} \mathbb{E}[\mathbb{I}(\mathcal{E}) \tau_i^\ast \alpha_{i,j}^\ast + \sum_{i \in C_i \in \mathcal{E}} \mathbb{E}[\mathbb{I}(\mathcal{E}) \tau_i^\ast \alpha_{i,j}^\ast + N^2 \delta T] 
\leq \sum_{i \in C_i \in \mathcal{E}} \mathbb{T_i \alpha_{i,j}^\ast} + \sum_{i \in C_i \in \mathcal{E}} \mathbb{T_i \alpha_{i,j}^\ast} + (\alpha_0 + N^2 \delta) T 
\leq c(G) \left( \sum_{i \in C_i \in \mathcal{E}} \log \frac{R}{\delta \alpha_{i,j}^\ast} + \sum_{i \in C_i \in \mathcal{E}} \log \frac{R}{\delta \alpha_{i,j}^\ast} \right) + (\alpha_0 + N^2 \delta) T
\leq c(G) N \log \frac{R}{\alpha_0} + (\alpha_0 + N^2 \delta) T
\]
The above calculation holds for any value of \( \alpha_0 > 0 \). Setting \( \alpha_0 = \sqrt{\frac{c(G) N}{T}} \) and \( \delta = \sqrt{\frac{c(G) N}{T N^2}} \), we get
Theorem 9 Let $G = (L, H)$ be an $N$ by $M$ partial-monitoring game. Assume that there exist two neighboring actions $i$ and $j$ such that $\ell_i - \ell_j \notin \text{Im} (S_{(i,j)})$. Then there exists a problem dependent constant $c(G)$ such that for any algorithm $A$ and time horizon $T$ there exists an opponent strategy $p$ such that the expected regret satisfies

$$E[R_T(A, p)] \geq c(G)T^{2/3}.$$ 

Proof: Without loss of generality we can assume that the two neighbor cells in the condition are $C_1$ and $C_2$. Let $C_3 = C_1 \cap C_2$. For $i = 1, 2, 3$, let $A_i$ be the set of actions associated with cell $C_i$. Note that $A_3$ may be the empty set. Let $A_4 = A \setminus (A_1 \cup A_2 \cup A_3)$. By our convention for naming loss vectors, $\ell_1$ and $\ell_2$ are the loss vectors for $C_1$ and $C_2$, respectively. Let $L_3$ collect the loss vectors of actions which lie on the open segment connecting $\ell_1$ and $\ell_2$. It is easy to see that $L_3$ is the set of loss vectors that correspond to the cell $C_3$. We define $L_4$ as the set of all the other loss vectors. For $i = 1, 2, 3, 4$, let $k_i = |A_i|$.

Let $S = S_{i,j}$ the signal matrix of the neighborhood action set of $C_1$ and $C_2$. It follows from the assumption of the theorem that $\ell_2 - \ell_1 \notin \text{Im}(S^T)$. Thus, $\{\rho (\ell_2 - \ell_1) : \rho \in \mathbb{R}\} \notin \text{Im}(S^T)$, or equivalently, $(\ell_2 - \ell_1)\perp \notin \text{Ker}(S)$, where we used that $(\text{Im}(M))^\perp = \text{Ker}(M^T)$. Thus, there exists a vector $v$ such that $v \in \text{Ker}(S)$ and $(\ell_2 - \ell_1)\top v \neq 0$. By scaling we can assume that $((\ell_2 - \ell_1)\top v) = 1$. Note that since $v \in \text{Ker}(S)$ and the rowspace of $S$ contains the vector $(1, 1, \ldots, 1)$, the coordinates of $v$ sum up to zero.

Let $p_0$ be an arbitrary probability vector in the relative interior of $C_3$. It is easy to see that for any $\varepsilon > 0$ small enough, $p_1 = p_0 + \varepsilon v \in C_2 \setminus C_1$ and $p_2 = p_0 - \varepsilon v \in C_2 \setminus C_1$.

Let us fix a deterministic algorithm $A$ and a time horizon $T$. For $i = 1, 2$, let $R_T^{(i)}$ denote the expected regret of the algorithm under opponent strategy $p_i$. For $i = 1, 2$ and $j = 1, \ldots, 4$, let $N_j^i$ denote the expected number of times the algorithm chooses an action from $A_j$, assuming the opponent plays strategy $p_i$.

From the definition of $L_3$ we know that for any $\ell \in L_3$, $\ell - \ell_1 = \eta \ell_2 - \ell_1$ and $\ell - \ell_2 = (1 - \eta) (\ell_2 - \ell_1)$ for some $0 < \eta < 1$. Let $\lambda_1 = \min_{\ell \in L_3} \eta$ and $\lambda_2 = \min_{\ell \in L_3} (1 - \eta)$ and $\lambda = \min(\lambda_1, \lambda_2)$ if $L_3 \neq \emptyset$ and let $\lambda = 1/2$, otherwise. Finally, let $\beta_1 = \min_{\ell \in L_3} (\ell - \ell_1)\top p_1$ and $\beta = \min(\beta_1, \beta_2)$. Note that $\lambda, \beta > 0$.

As the first step of the proof, we lower bound the expected regret $R_T^{(1)}$ and $R_T^{(2)}$ in terms of the values $N_j^i, \varepsilon, \lambda$ and $\beta$:

$$R_T^{(1)} \geq N_3^2 (\ell_2 - \ell_1)\top p_1 + N_3^2 \lambda (\ell_2 - \ell_1)\top p_1 + N_4^1 \beta \geq \lambda (N_3^2 + N_4^1) \varepsilon + N_4^1 \beta,$$

$$R_T^{(2)} \geq N_3^2 (\ell_1 - \ell_2)\top p_2 + N_3^2 \lambda (\ell_1 - \ell_2)\top p_2 + N_4^2 \beta \geq \lambda (N_3^2 + N_4^2) \varepsilon + N_4^2 \beta. \quad (6)$$

For the next step, we need the following lemma.

Lemma 10 There exists a (problem dependent) constant $c$ such that the following inequalities hold:

$$N_1^2 \geq N_1^4 - cT \varepsilon \sqrt{N_4^1}, \quad N_2^2 \geq N_2^4 - cT \varepsilon \sqrt{N_4^1}, \quad N_3^2 \geq N_3^4 - cT \varepsilon \sqrt{N_4^1}, \quad N_4^3 \geq N_4^2 - cT \varepsilon \sqrt{N_4^1}.$$ 

Proof: (Lemma 10) For any $1 \leq t \leq T$, let $f^t = (f_1, \ldots, f_t) \in \Sigma^t$ be a feedback sequence up to time step $t$. For $i = 1, 2$, let $p_i^t$ be the probability mass function of feedback sequences of length $T - 1$ under opponent strategy $p_i$ and algorithm $A$. We start by upper bounding the difference between values under the
two opponent strategies. For \( i \neq j \in \{1, 2\} \) and \( k \in \{1, 2, 3\} \),

\[
N_k^i - N_k^j = \sum_{f^{t-1}} \left( p^*_i(f^{t-1}) - p^*_j(f^{t-1}) \right) \sum_{t=0}^{T-1} \mathbb{I}(A(f^t) \in A_k)
\]

\[
\leq \sum_{f^{t-1}} \left( p^*_i(f^{t-1}) - p^*_j(f^{t-1}) \right) \sum_{t=0}^{T-1} \mathbb{I}(A(f^t) \in A_k)_{p^*_i(f^{t-1}) - p^*_j(f^{t-1}) \geq 0}
\]

\[
\leq T \sum_{f^{t-1}} \left( p^*_i(f^{t-1}) - p^*_j(f^{t-1}) \right) = \frac{T}{2} \| p^*_i - p^*_j \|_1
\]

\[
\leq \sqrt{\text{KL}(p^*_i \| p^*_j) / 2}, \tag{7}
\]

where \( \text{KL}(\cdot \| \cdot) \) denotes the Kullback-Leibler divergence and \( \| \cdot \|_1 \) is the \( L_1 \)-norm. The last inequality follows from Pinsker’s inequality (Cover and Thomas [2006]). To upper bound \( \text{KL}(p^*_i \| p^*_2) \) we use the chain rule for KL-divergence. By overloading \( p_i \) so that \( p_i(f^{t-1}) \) denotes the probability of feedback sequence \( f^{t-1} \) under opponent strategy \( p_i \) and algorithm \( A \), and \( p_i(f_t|f^{t-1}) \) denotes the conditional probability of feedback \( f_t \in \Sigma \) given that the past feedback sequence was \( f^{t-1} \), again under \( p_i \) and \( A \). With this notation we have

\[
\text{KL}(p^*_i \| p^*_2) = \sum_{t=1}^{T-1} \sum_{f^{t-1}} p^*_i(f^{t-1}) \sum_{f_t} p^*_i(f_t|f^{t-1}) \log \frac{p^*_i(f_t|f^{t-1})}{p^*_2(f_t|f^{t-1})}
\]

\[
= \sum_{t=1}^{T-1} \sum_{f^{t-1}} p^*_i(f^{t-1}) \sum_{f_t} \mathbb{I}(A(f^{t-1}) \in A_i) \sum_{f_t} p^*_i(f_t|f^{t-1}) \log \frac{p^*_i(f_t|f^{t-1})}{p^*_2(f_t|f^{t-1})} \tag{8}
\]

Let \( \alpha_{f_t}^T \) be the row of \( S \) that corresponds to the feedback symbol \( f_t \). Assume \( k = A(f^{t-1}) \). If the feedback set of action \( k \) does not contain \( f_t \) then trivially \( p^*_i(f_t|f^{t-1}) = 0 \) for \( i = 1, 2 \). Otherwise \( p^*_i(f_t|f^{t-1}) = \alpha_{f_t}^T p_i \).

Since \( p_1 - p_2 = 2\varepsilon v \) and \( v \in \text{Ker} S \), we have \( \alpha_{f_t}^T v = 0 \) and thus, if the choice of the algorithm is in either \( A_1, A_2 \) or \( A_3 \), then \( p^*_i(f_t|f^{t-1}) = p^*_2(f_t|f^{t-1}) \). It follows that the inequality chain can be continued from (8) by writing

\[
\text{KL}(p^*_i \| p^*_2) \leq \sum_{t=1}^{T-1} \sum_{f^{t-1}} p^*_i(f^{t-1}) \mathbb{I}(A(f^{t-1}) \in A_4) \sum_{f_t} p^*_i(f_t|f^{t-1}) \log \frac{p^*_i(f_t|f^{t-1})}{p^*_2(f_t|f^{t-1})}
\]

\[
\leq c_1 \varepsilon^2 \sum_{t=1}^{T-1} \sum_{f^{t-1}} p^*_i(f^{t-1}) \mathbb{I}(A(f^{t-1}) \in A_4) \tag{9}
\]

\[
\leq c_1 \varepsilon^2 N_4^i.
\]

In (9) we used Lemma T2 (see Appendix) to upper bound the KL-divergence of \( p_1 \) and \( p_2 \). Flipping \( p^*_1 \) and \( p^*_2 \) in (7) we get the same result with \( N_4^2 \). Reading together with the bound in (7) we get all the desired inequalities.

Now we can continue lower bounding the expected regret. Let \( r = \argmin_{i \in \{1, 2\}} N_i^j \). It is easy to see that for \( i = 1, 2 \) and \( j = 1, 2, 3 \),

\[
N_j^i \geq N_j^r - c_2 T \varepsilon \sqrt{N_4^i}.
\]

If \( i \neq r \) then this inequality is one of the inequalities from Lemma 10. If \( i = r \) then it is a trivial lower bounding by subtracting a positive value. From (6) we have

\[
R_{i}^{(r)} \geq \lambda (N_{3-i}^i + N_3^i) \varepsilon + N_i^r \beta
\]

\[
\geq \lambda (N_{3-i}^i + c_2 T \varepsilon \sqrt{N_4^i} + N_3^i - c_2 T \varepsilon \sqrt{N_4^i} \varepsilon + N_i^r \beta
\]

\[
= \lambda (N_{3-i}^i + N_3^i - 2c_2 T \varepsilon \sqrt{N_4^i} \varepsilon + N_i^r \beta.
\]
Now assume that, at the beginning of the game, the opponent randomly chooses between strategies \( p_1 \) and \( p_2 \) with equal probability. The the expected regret of the algorithm is lower bounded by

\[
R_T = \frac{1}{2} \left( R_T^{(1)} + R_T^{(2)} \right) \\
\geq \frac{1}{2} \lambda (N_1^* + N_2^* + 2N_3^* - 4c_2T\varepsilon \sqrt{N_4^*})\varepsilon + N_4^* \beta \\
\geq \frac{1}{2} \lambda (N_1^* + N_2^* + N_3^* - 4c_2T\varepsilon \sqrt{N_4^*})\varepsilon + N_4^* \beta \\
= \frac{1}{2} \lambda (T - N_4^* - 4c_2T\varepsilon \sqrt{N_4^*})\varepsilon + N_4^* \beta.
\]

Choosing \( \varepsilon = c_3 T^{-1/3} \) we get

\[
R_T \geq \frac{1}{2} \lambda c_3 T^{2/3} - \frac{1}{2} \lambda N_4^* c_3 T^{-1/3} - 2\lambda c_2 c_3^2 T^{1/3} \sqrt{N_4^*} + N_4^* \beta \\
\geq T^{2/3} \left( \left( \beta - \frac{1}{2} \lambda c_3 \right) \frac{N_4^*}{T^{2/3}} - 2\lambda c_2 c_3^2 \sqrt{\frac{N_4^*}{T^{2/3}}} + \frac{1}{2} \lambda c_3 \right) \\
= T^{2/3} \left( \left( \beta - \frac{1}{2} \lambda c_3 \right) x^2 - 2\lambda c_2 c_3^2 x + \frac{1}{2} \lambda c_3 \right),
\]

where \( x = \sqrt{N_4^* / T^{2/3}} \). Now we see that \( c_3 > 0 \) can be chosen to be small enough, independently of \( T \), so that, for any choice of \( x \), the quadratic expression in the parenthesis is bounded away from zero, and simultaneously, \( \varepsilon \) is small enough so that the threshold condition in Lemma 12 is satisfied, completing the proof of Theorem 9.

7 Discussion

In this we paper we classified all finite partial-monitoring games under stochastic environments, based on their minimax regret. We conjecture that our results extend to non-stochastic environments. This is the major open question that remains to be answered.

One question which we did not discuss so far is the computational efficiency of our algorithm. The issue is twofold. The first computational question is how to efficiently decide which of the four classes a given game belongs to. The second question is the computational efficiency of BALATON for a fixed easy game. Fortunately, in both cases an efficient implementation is possible, i.e., in polynomial time by using a linear program solver (e.g., the ellipsoid method [Papadimitriou and Steiglitz, 1998]).

Another interesting open question is to investigate the dependence of regret on quantities other than \( T \) such as the number of actions, the number of outcomes, and more generally the structure of the loss and feedback matrices.

Finally, let us note that our results can be extended to a more general framework, similar to that of [Pallavi et al., 2011], in which a game with \( N \) actions and \( M \)-dimensional outcome space is defined as a tuple \( G = (L, S_1, \ldots, S_N) \). The loss matrix is \( L \in \mathbb{R}^{N \times M} \) as before, but the outcome and the feedback are defined differently. The outcome \( y \) is an arbitrary vector from a bounded subset of \( \mathbb{R}^M \) and the feedback received by the learner upon choosing action \( i \) is \( O_i = S_i y \).

Appendix

Proof: (Lemma 8)

1. In an elimination set, we eliminate every action whose cell is contained in a closed half space. Let us assume that \( j \in A_i \) is being eliminated. According to the definition of \( A_i \), \( C_i \subset C_j \) and thus \( C_i \) is also contained in the half space.

2. First let us assume that \( p^* \) is not in the affine subspace spanned by \( C_i \). Let \( p \) be an arbitrary point in the relative interior of \( C_i \). We define the point \( p' = p + \varepsilon (p - p^*) \). For a small enough \( \varepsilon > 0 \), \( p' \in C_k \in A_i \), and at the same time, \( p' \notin C_i \). Thus we have

\[
\ell_k^T (p + \varepsilon (p - p^*)) \leq \ell_i^T (p + \varepsilon (p - p^*))
\]

\[
(1 + \varepsilon) \ell_k^T p - \varepsilon \ell_k^T p^* \leq (1 + \varepsilon) \ell_i^T p - \varepsilon \ell_i^T p^*
\]

\[
-\varepsilon \ell_k^T p^* \leq -\varepsilon \ell_i^T p^*
\]

\[
\ell_k^T p^* \geq \ell_i^T p^*
\]

\[
\alpha_{k,j} \geq \alpha_{i,j},
\]

where we used that \( \ell_k^T p = \ell_i^T p \).

For the case when \( p^* \) lies in the affine subspace spanned by \( C_i \), We take a hyperplane that contains the affine subspace. Then we take an infinite sequence \( (p_n) \) such that every element of the sequence is in the same side of the hyperplane, \( p_n \neq p^* \) and the sequence converges to \( p^* \). Then the statement is true for every element \( p_n \) and, since the value \( \alpha_{r,s} \) is continuous in \( p \), the limit has the desired property as well.

The following lemma concerns the problem of producing an estimate of an unknown mean of some stochastic process with a given relative error bound and with high probability in a sample-efficient manner. The procedure is a simple variation of the one proposed by [Mnih et al. 2008]. The main differences are that here we deal with martingale difference sequences shifted by an unknown constant, which becomes the common mean, whereas [Mnih et al. 2008] considered an i.i.d. sequence. On the other hand, we consider the case when we have a known upper bound on the predictable variance of the process, whereas one of the main contributions of [Mnih et al. 2008] was the lifting of this assumption. The proof of the lemma is omitted, as it follows the same lines as the proof of results of [Mnih et al. 2008] (the details of these proofs are found in the thesis of [Mnih 2008]), the only difference being, that here we would need to use Bernstein’s inequality for martingales, in place of the empirical Bernstein inequality, which was used by [Mnih et al. 2008].

Lemma 11 Let \( (\mathcal{F}_t) \) be a filtration on some probability space, and let \( (X_t) \) be an \( \mathcal{F}_t \)-adapted sequence of random variables. Assume that \( (X_t) \) is such that, almost surely, the range of each random variable \( X_t \) is bounded by \( R > 0 \), \( \mathbb{E}[X_t|\mathcal{F}_{t-1}] = \mu_t \), and \( \forall t \mathbb{V}[X_t|\mathcal{F}_{t-1}] \leq \sigma^2 \) a.s., where \( R, \mu_t \neq 0 \) and \( \sigma^2 \) are non-random constants. Let \( p > 1, \varepsilon > 0, 0 < \delta < 1 \) and let

\[
L_n = (1 + \varepsilon) \max_{1 \leq t \leq n} \{|X_t| - c_t\}, \quad \text{and} \quad U_n = (1 - \varepsilon) \min_{1 \leq t \leq n} \{|X_t| + c_t\},
\]

where \( c_t = c(\sigma, R, t, \delta) \), and \( c(\cdot) \) is defined in (1). Define the estimate \( \hat{\mu}_n \) of \( \mu \) as follows:

\[
\hat{\mu}_n = \text{sgn}(\overline{X}_n) \frac{(1 + \varepsilon)L_n + (1 - \varepsilon)U_n}{2}.
\]

Denote the stopping time \( \tau = \min \{ n : L_n \geq U_n \} \). Then, with probability at least \( 1 - \delta \),

\[
|\hat{\mu}_\tau - \mu| \leq \varepsilon |\mu| \quad \text{and} \quad \tau \leq C \cdot \max \left( \frac{\sigma^2}{\varepsilon^2 |\mu|^2}, \frac{R}{\varepsilon |\mu|} \right) \left( \log \frac{1}{\delta} + \log \frac{R}{\varepsilon |\mu|} \right),
\]

where \( C > 0 \) is a universal constant.

Lemma 12 Fix a probability vector \( p \in \Delta_M \), and let \( \varepsilon \in \mathbb{R}^M \) such that \( p - \varepsilon, p + \varepsilon \in \Delta_M \) also holds. Then

\[
\text{KL}(p - \varepsilon, p + \varepsilon) = O(\varepsilon^2) \quad \text{as} \ \varepsilon \to 0.
\]

The constant and the threshold in the \( O(\cdot) \) notation depends on \( p \).
Proof: Since \( p, \ p + \epsilon, \) and \( p - \epsilon \) are all probability vectors, notice that \( |\epsilon(i)| \leq p(i) \) for \( 1 \leq i \leq M \). So if a coordinate of \( p \) is zero then the corresponding coordinate of \( \epsilon \) has to be zero as well. As zero coordinates do not modify the KL divergence, we can assume without loss of generality that \( |\epsilon(i)| \leq p(i)/2 \). Also note that the coordinates of \( \epsilon = (p + \epsilon) - p \) have to sum up to zero. By definition,

\[
\text{KL}(p - \epsilon||p + \epsilon) = \sum_{i=1}^{M} (p(i) - \epsilon(i)) \log \frac{p(i) - \epsilon(i)}{p(i) + \epsilon(i)}.
\]

We write the term with the logarithm

\[
\log \frac{p(i) - \epsilon(i)}{p(i) + \epsilon(i)} = \log \left( 1 - \frac{\epsilon(i)}{p(i)} \right) - \log \left( 1 + \frac{\epsilon(i)}{p(i)} \right),
\]

so that we can use that, by second order Taylor expansion around 0, \( \log(1 - x) - \log(1 + x) = -2x + r(x) \), where \( |r(x)| \leq c|x|^3 \) for \( |x| \leq 1/2 \) and some \( c > 0 \). Combining these equations, we get

\[
\text{KL}(p - \epsilon||p + \epsilon) = \sum_{i=1}^{M} (p(i) - \epsilon(i)) \left[ -2\epsilon(i) + r \left( \frac{\epsilon(i)}{p(i)} \right) \right]
\]

\[
= \sum_{i=1}^{M} -2\epsilon(i) + \sum_{i=1}^{M} 2\epsilon^2(i) \frac{1}{p(i)} + \sum_{i=1}^{M} (p(i) - \epsilon(i)) \frac{\epsilon(i)}{p(i)} - 2\epsilon(i) + \frac{\epsilon^2(i)}{p(i)}.
\]

Here the first term is 0, letting \( p = \min_{i \in \{1, \ldots, M\}} p(i) \) the second term is bounded by \( 2 \sum_{i=1}^{M} \epsilon^2(i) / p = (2/p) ||\epsilon||_2^2 \), and the third term is bounded by

\[
\sum_{i=1}^{M} (p(i) - \epsilon(i)) \frac{\epsilon(i)}{p(i)} \leq c \sum_{i=1}^{M} \frac{p(i) - \epsilon(i)}{p^3(i)} |\epsilon(i)|^3
\]

\[
\leq c \sum_{i=1}^{M} \frac{|\epsilon(i)|}{p^2(i)} \epsilon^2(i)
\]

\[
\leq c \frac{M}{2} \sum_{i=1}^{M} \frac{1}{p^2} \epsilon^2(i) = \frac{c}{2p^2} ||\epsilon||_2^2.
\]

Hence, \( \text{KL}(p - \epsilon||p + \epsilon) \leq \frac{4 + c}{2p} ||\epsilon||_2^2 = O(||\epsilon||_2^2) \).
